ABSTRACT

Mesothelioma, a malignant cancer affecting the pleura, peritoneum, and other organs, remains a major health challenge due to its poor prognosis. Proteins like Bcl-2A1 and Bcl2-L-10-2 contribute to apoptotic resistance, while NPM2 and CLDN-4 serve as potential biomarkers and therapeutic targets. This study used in silico methods to analyze these proteins, aiming to uncover molecular insights for targeted treatments. Using FASTA sequences from NCBI and PDB, 3D models were developed via homology modeling with Modeller 10.4 and validated using SAVES v6.0 and ProSA. Active site predictions with CASTp revealed five potential binding pockets per protein. Docking studies with Alimta and Bevacizumab identified key amino acids involved in drug interactions: LEU105, GLN23, and PHE43 in Bcl-2A1; ARG38, GLY23, and TYR17 in Bcl2-L-10-2; ARG12, TRP15, and GLY30 in NPM2; and VAL132, GLY163, and LEU73 in CLDN-4. These findings highlight crucial molecular targets, offering insights for developing more effective mesothelioma therapies.

INTRODUCTION

Mesothelioma is a cancer originating from the mesothelium, a protective layer covering internal organs, most commonly affecting the lungs' pleura, but also found in the abdomen, heart, and testicles (Mott, 2012). The disease's primary cause is asbestos exposure, a mineral once widely used for its heat resistance, now known to induce mesothelioma after a latency period of around 40 years. Symptoms include shortness of breath, swollen abdomen, chest pain, and weight loss, with over 80% of cases linked to asbestos (Robinson et al., 2005). The history of mesothelioma aligns with the recognition of asbestos's carcinogenic effects, beginning with early cases in the 1920s and evolving through increased awareness and regulation in the 1960s and 70s (McDonald & McDonald, 1996; Zellos & Christiani, 2004). While asbestos use has declined in many regions, its historical prevalence continues to contribute to ongoing cases (Huang et al., 2023). Mesothelioma types are categorized by location—pleural (80-90% of cases), peritoneal (10-15%), pericardial (less than 1%), and testicular (less than 1%)—and cell type—epithelioid (50-70% of cases), sarcomatoid (10-20%), and biphasic (20%) (Molinari n.d.; Katy Moncivais, n.d.). Pathophysiologically, asbestos exposure triggers inflammation and genetic damage in mesothelial cells through mechanisms involving TNF- α and NF- κ B pathways, leading to continuous cell proliferation and cancer development (Carbone1, 2009).

Mesothelioma is an aggressive form of cancer that develops in the mesothelium, the protective lining of internal organs. It most commonly affects the lungs (pleural mesothelioma) but can also occur in the abdomen (peritoneal mesothelioma), the heart (pericardial mesothelioma), or the testicles (testicular mesothelioma). Symptoms differ depending on the type: pleural mesothelioma often causes a persistent cough, chest discomfort, and difficulty breathing; peritoneal mesothelioma may result in abdominal pain, nausea, and swelling; pericardial mesothelioma can lead to chest pain and fluid buildup around the heart; while testicular mesothelioma may present with scrotal swelling or hydrocele. Early diagnosis is challenging due to the disease's subtle initial symptoms and the long latency period between exposure to asbestos and the appearance of symptoms. (Anon., n.d.). The diagnosis often relies on a combination of imaging methods such as X-rays identify effusions and masses; CT scans provide detailed tumor localization; MRIs offer superior soft tissue contrast; and PET scans assess metabolic activity to detect metastases. A definitive diagnosis is usually made through a thoracoscopic biopsy, a minimally invasive procedure that involves inserting a camera and biopsy tools into the chest cavity to obtain tissue samples (Andrea Bianco, 2018). Given its aggressive nature, mesothelioma is predominantly diagnosed at an advanced stage, making a complete cure challenging. Treatment strategies usually include a multimodal approach—surgery, chemotherapy, and radiation therapy—tailored to the disease's stage, patient health, and tumor extent. Emerging treatments, particularly in immunotherapy, show promise in targeting cancer cells more precisely based on individual tumor characteristics. Claudin-4 (CLDN4) plays a

significant role in cancer progression, including mesothelioma. It is involved in forming tight junctions (TJs) that regulate cell-cell adhesion and barrier function. Overexpression of CLDN4 in various cancers contributes to tumor progression by affecting the tumor microenvironment, inhibiting immune cell infiltration, and limiting drug penetration, thus contributing to drug resistance. CLDN4's non-TJ functions, such as interacting with integrin β 1 and YAP, promote tumor cell proliferation and epithelial-mesenchymal transition (EMT). Targeting CLDN4 with molecular therapies like anti-CLDN4 antibodies shows potential for improving cancer treatment (Rina Fujiwara-Tani, 2023). The Bcl-2 family of proteins, including Bcl-2-related protein A1 (Bcl-2A1), plays a vital role in regulating apoptosis and contributes to cancer progression and resistance to therapy. Bcl-2A1, related to other Bcl-2 proteins, contributes to chemoresistance by inhibiting apoptosis, a common issue in cancer treatment. It functions through mitochondrial pathways to prevent cytochrome C release and caspase activation. Overexpression or dysregulation of Bcl-2 family members often leads to chemotherapy resistance, impairing drug-induced apoptosis (Santanu Maji, 2018). Nucleoplasmin-2 (NPM2), particularly its isoform 2, is implicated in cancer progression, including mesothelioma. Through its interaction with histones, NPM2 is involved in chromatin regulation and gene transcription. High NPM2 expression in tumors is associated with poorer survival outcomes, suggesting its potential as a prognostic marker. NPM2 may facilitate histone deacetylation, impacting gene expression related to tumor suppression and contributing to cancer progression (Wu, 2022). Bcl2-like protein 10 (Bcl2-L-10), an isoform of the Bcl-2 family, lacks the BH3 domain but contains BH4, BH1, and BH2 domains. It inhibits apoptosis by preventing cytochrome C release and mitochondrial membrane collapse, distinct from traditional Bcl-2 proteins. Bcl2-L-10's role is specific to blocking apoptosis through the mitochondrial pathway, without affecting death receptor-mediated apoptosis (Hong Zhang, 2001). This specificity highlights its potential as a target for cancer therapies aiming to manipulate apoptotic pathways.

MATERIALS AND METHODS

Homology modelling: The target and template proteins were chosen using biological databases, including NCBI, BLAST, PDB, and ExPASy. Selection criteria included proteins with fewer than 250 amino acids, those that had been reviewed, and those with relevant publications.

Model Generation and validation: Model generation and validation were performed using several tools: SWISS-MODEL, an automated platform for constructing comparative models of 3D protein structures; Discovery Studio, a software suite developed by Dassault Systèmes BIOVIA for simulating small molecules and macromolecules; SAVES v6.0, a comprehensive toolkit featuring ERRAT, VERIFY3D, PROVE, PROCHECK, and WHAT CHECK for evaluating various stereochemical parameters of protein structures; and PROSA, an interactive tool designed to detect errors in 3D protein structures.

Active site prediction: The active sites of the generated models were predicted using CASTp, an online platform that provides tools for identifying, defining, and analyzing the geometric and topological properties of protein structures.

Selection of Ligands: Ligands for molecular docking were chosen from PubChem, a public database providing data on chemical compounds and their biological interactions, developed as part of the US National Institutes of Health (NIH) Molecular Libraries Roadmap Initiatives. The selected ligands included Alimta and Bevacizumab.

Docking of Ligand and Macromolecule: Docking was carried out using PyRx, a virtual screening tool for docking small-molecule libraries to macromolecules and identifying lead compounds with desired biological functions. Autodock Vina was employed through the command prompt to split the ligands, while BIOVIA Discovery

Studio Visualizer was used to visualize the interactions between the ligands and the protein.

RESULTS AND DISCUSSION

Homology modelling: Selection of target protein: The accession codes “NP_001296.1”, “NP_004040.1”, “NP_001273610.1”, and “NP_065129.1” were obtained from NCBI to retrieve the FASTA sequences of Claudin-4, Bcl-2-related protein A1, Nucleoplasmin-2 isoform 2, and Bcl-2-like protein 10 isoform 2 from UniProtKB/Swiss-Prot. NCBI provides genomic data, while ExPASy, hosted by the Swiss Institute of Bioinformatics, offers protein analysis tools. The FASTA sequences will be used for homology modeling to generate 3D models of the target proteins, aiding structural and functional studies (Consortium, 2023).

Selection of template protein: A BLAST search using the FASTA sequence identified Homo sapiens proteins with query coverage over 80% and identity above 27%. Protein accession codes 6RJP_A, 4B4S_A, 3T30_A, and 7TDM_A were entered into RCSB PDB to assess unmodeled regions, and those with minimal unmodeled regions were selected. These proteins, with 85%-100% query coverage and 100% identity, were used as templates for Claudin-4, Bcl-2-related protein A1, Nucleoplasmin-2 isoform 2, and Bcl-2-like protein 10 isoform 2 (Altschul *et al.*, 1990; Newell *et al.*, 2013). The selected template proteins include Bfl-1 in complex with an alpha-helical peptide, which has 85% query coverage and 100% identity with a small unmodeled region. The Bcl-2: Bim BH3 complex shows 100% query coverage and identity with minimal unmodeled regions. Human nucleoplasmin (Npm2), a histone chaperone in oocytes and early embryos, also has 100% query coverage and identity but displays some unmodeled regions at three positions. Lastly, the CryoEM structure of the sFab COP-2 complex with claudin-4 has 100% query coverage and identity with a very small unmodeled region.

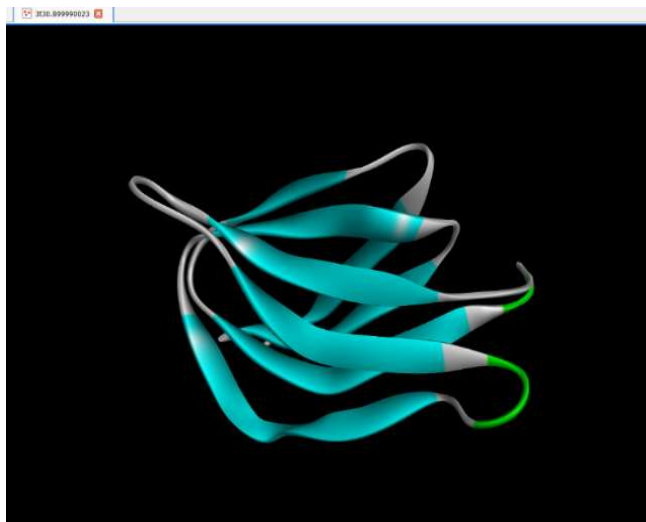

Figure 1(c). Structure of Nucleoplasmin-2-isoform homology modelling

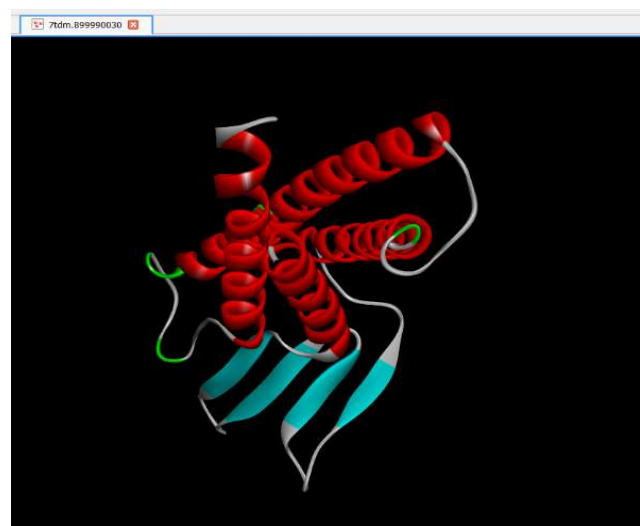

Figure 1(d): Structure of Claudin-4 generated by generated by homology modeling

Multiple sequence alignment: A sequence alignment was performed using Clustal Omega by pasting the FASTA sequences of the target and template proteins. Clustal Omega is an automated multiple-sequence alignment tool that efficiently aligns two or more sequences (Madeira *et al.*, 2022). The alignment file was generated in Pearson/FASTA and Clustal W formats, with the character count format selected as the output.

Figure 3(a),(b),(c),(d). Result summaries of PROCHECK

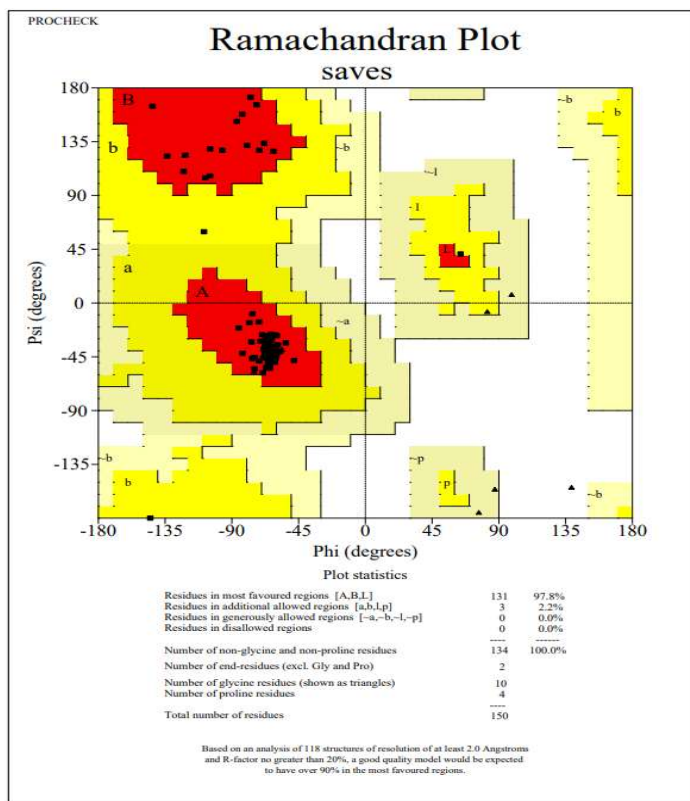

Model Generation: The alignment.ali and model-default.py files necessary for a model generation were created by modifying the code to include data for the selected target and template proteins. Using Modeller 10.4 software, the alignment was performed, and models in PDB format were generated. Modeller, a software tool used for comparative modeling of protein structures, uses simple alignment files to calculate models containing all non-hydrogen atoms, employing the PIR format for sequence reading and writing. The generated models were assessed, and the one with the least objective function was selected. Visualization of the best model was conducted in Discovery Studio (BIOVIA, 2021). Model Validation: Model validation is done using Saves 6.0 and the following results are obtained in Verify 3D (Fig 4.16) and ProCheck (Fig 4.17). The Ramachandran plots having 97.8%, 92.2%, 95.9% & 92.5% residues in the favored region are also downloaded (Fig 4.18)

Verify 3D is a method used to assess the quality of a protein model. A model is considered of good quality if over 80% of its amino acids achieve a score of ≥ 0.2 in the 3D/1D profile. However, Verify 3D alone is insufficient for comprehensive validation; other parameters must also be examined. The model failed the Verify 3D assessment (Fig. 4.16), but further evaluation using Procheck (Laskowski R A, 1993) analyzed additional parameters. Since each model has over 90% residues in the highly favoured region, in the Ramachandran plot they are valid for further studies. Further model validation was performed using ProSA web, which shows the graphs below. Figure 1.9 shows the graphs of overall model quality specifying the Z score and Figure 4.20 local model quality. The ProSA program (Sippl, 2007) is a widely used tool for refining and validating experimental protein structures using atomic coordinates in PDB format. The "Overall Model Quality" graphs display z-scores, indicating overall model quality, with X-ray crystallography (light blue) and NMR spectroscopy (dark blue) z-scores plotted against protein length. The z-scores for Bcl-2-related protein A1, Nucleoplasmin-2 isoform 2, Bcl-2-like protein 10 isoform 2, and Claudin-4 are -6.83, -6.64, -3.76, and -2.59, respectively. "Local Model Quality" energy plots show residue energies across the amino acid sequence, with positive values suggesting problematic regions. Bcl-2-related protein A1, Nucleoplasmin-2 isoform 2, and Bcl-2-like protein 10 isoform 2 have only negative values, while Claudin-4 shows mostly negative values with a few peaks. The models are validated by their negative z-scores and predominantly negative energy plots.

Active-site prediction: CASTp is used to visualize and tabulate protein pockets. The Computed Atlas of Surface Topography of Proteins (CASTp) server provides information about a protein's topographic features, identifying channels, pockets, and cavities. A cavity is an inner space inaccessible to solvent, while pockets are surface concavities where the solvent can enter, potentially serving as active sites or receptor interaction points. Protein structures in PDB format and a probe radius (default 1.4 Å) are inputs to CASTp, which predicts the active sites based on these features. The Computed Atlas of Surface Topography of Proteins (CASTp) server provides insights into the topographic features of proteins, identifying cavities, pockets, and channels within protein structures (al, 2018). Cavities are interior voids inaccessible to the solvent, while pockets are surface concavities accessible to the solvent, potentially serving as active sites (Vadija *et al.*, 2016). Using protein structures in PDB format and a probe radius (default 1.4 Å), CASTp outputs details on surface pockets and cavities, including volumes, areas, and constituent atoms. Active site residues and cavity volumes for Bcl-2-related protein A1, Nucleoplasmin-2 isoform 2, Bcl-2-like protein 10 isoform 2, and Claudin-4 were predicted and tabulated based on pocket evaluation with CASTp.

Selection of Ligands: Alimta and Bevacizumab are drugs used in the treatment of the cancer Mesothelioma. The 3D conformations of the drugs were downloaded from PubChem, a public database providing information on chemical substances and their biological activities, initiated in 2004 as a part of the US National Institutes of Health (NIH) Molecular Libraries Roadmap Initiatives (Kim, 2023). The drugs were downloaded in the sdf format and further converted to the PDB format to perform docking and study the interactions between each drug (acting as a ligand) and the proteins.

Docking of ligand and macromolecule: Docking of ligands and macromolecule (protein) was performed using PyRx. A grid was formed surrounding the entire structure and Vina was run to give the results in the form of a table containing the ligand's bond affinity and rmsd values. PyRx is a software used for docking studies. The drugs (downloaded in step) are docked as ligands and the protein (target) is docked as the macromolecule. Using Vina Wizard, a Grid of suitable dimensions with respective suitable centers is generated enclosing the entire protein containing the active sites. (Vadija *et al.*, 2016) Upon further running the program, a table is obtained containing the ligands, their binding affinities, and rmsd values. Rmsd refers to the root mean square deviation values and only those proteins containing 0 as rmsd values must be considered.

Binding affinity refers to the strength of the binding interaction between a protein and its ligand. A higher binding affinity indicates a weaker attraction and binding between the target molecule and ligand. Therefore, binding affinities should be negative, with lower values indicating better results. Hence, for each ligand, the conformation with the least affinity and 0 rmsd value is selected. Splitting of ligand files: This operation was performed using Vina software and Command Prompt.

AutoDockVina is a software that can be utilized to split the ligand files in their PDBQT format based on their rmsd values and binding affinities. The command prompt uses “vina_split” as a command to execute the process of splitting. Each ligand file is split into 10 conformations, which can be further analyzed to find the ligands with the binding affinities and rmsd values, and these are used as ligands in the final step for studying the ligand-protein interactions.

Visualisation of interactions between ligands and protein: The interactions between ligands and proteins are visualized using Discovery Studio in the form of 2D and 3D structures as given below.

Interaction of Alimta & Bevacizumab with Bcl-2-related protein A1

bonds, and bonds formed due to attractive charges with the amino acid residues LEU105, LEU22, GLN23, LYS102, VAL21, CYS20, PHE43, VAL21 of Bcl-2A1.

Upon analysis of the types of bonds formed and the amino acids involved in bond formation (Table 4.6, 4.7), it was observed that the H-bond is formed predominantly by CYS20, VAL21, GLN23, and LEU22. It was also observed that most of the amino acids involved in bond formation belonged to pocket-2 and 3 (as seen in CASTp Table 4.1) indicating that the amino acid residues of pocket-2 and 3 can act

as good active sites for ligand binding and thus these amino acid residues could act as important sites for interaction of drugs with Bcl-2A1.

The ligand molecules exhibit the formation of Conventional Hydrogen bonds, Carbon-Hydrogen bonds, Pi-Donor Hydrogen bonds, Pi-Pi T-shaped bonds, Amide-Pi stacked bonds, Pi-Alkyl bonds, Pi-sigma bonds, Pi-Cation, Pi-Anion and Alkyl bonds with the amino acid residues ARG38, ALA42, ALA41, ARG98, ARG20, GLY23, THRI24, PRO22, GLU97, TYR17of Bcl2-L-10-2. Upon analysis of the types of bonds formed and the amino acids involved in bond formation (Table 4.8, 4.9), it was observed that the H-bond is formed predominantly by ARG38, ARG20, ARG98, GLY23, THRI24, and TYR17. It was also observed that most of the amino acids involved in bond formation belonged to pocket-2 (as seen in CASTp Table 4.2) indicating that the amino acid residues of pocket-2 can act as good active sites for ligand binding. Thus, these amino acid

residues could act as important sites for the interaction of drugs with Bcl2-L-10-2.

Interaction of Alimta & Bevacizumab with NPM2

| 8 | :UNK0 - A:VAL80 | 5.3195 | Hydrophobic | Pi-Alkyl | :UNK0 | A:VAL80 |

It was also observed that most of the amino acids involved in bond formation belonged to pocket-1,2,3 & 4 (as seen in CASTp Table 4.4) indicating that the amino acid residues of pocket-1,2,3 & 4 can act as good active sites for ligand binding and thus these amino acid residues could act as important sites for interaction of drugs with CLDN-4.

CONCLUSION

Mesothelioma, a cancer affecting the mesothelium lining various internal organs, presents a grim prognosis with a typical survival rate of 4 to 18 months post-diagnosis and a five-year survival rate of just 10 percent. Over the years, mesothelioma cases have surged by more than 36%, underscoring the urgent need for novel treatment options. Current therapies often fall short in managing advanced cases, leading to low survival probability and compromised quality of life for patients. Addressing this pressing global health challenge requires innovative drug development efforts. One promising avenue lies in personalized medicine, offering tailored interventions for mesothelioma patients. However, collaborative research endeavours are essential to bring accessible and effective drugs to fruition. Leveraging bioinformatics tools for in silico drug design presents a faster and more efficient alternative to traditional laboratory methods.

In the above context, this study is focused on elucidating the interactions between key proteins implicated in mesothelioma—such as Claudin-4, Bcl-2-related protein A1, nucleoplasmin-2 isoform 2, and bcl-2-like protein 10 isoform 2—and established mesothelioma drugs like Alimta and Bevacizumab. Utilizing homology modeling, we generated 3D structures of these proteins and conducted docking studies to identify critical binding residues. The findings highlight specific amino acid residues within these proteins—such as LEU105, LEU22, GLN23, LYS102, VAL21, CYS20, PHE43, and VAL21 in *Bcl-2A1*; ARG38, ALA42, ALA41, ARG98, ARG20, GLY23, THR124, PRO22, GLU97, and TYR17 in *Bcl2-L-10-2*; ARG12, ARG18, GLU7, THR16, CYS6, TRP15, TRP4, GLU92, GLU31, GLY30, LYS32, PHE87, and LEU88 in *NPM2*; and VAL132, CYS20, GLY163, VAL128, TRP26, ALA76, ARG27, LEU73, and VAL80 in *CLDN-4* as crucial for drug binding and potential inhibition of mesothelioma cell replication. By targeting these key residues, novel drugs may effectively disrupt mesothelioma progression, offering hope for improved patient outcomes.
